Abstract

The mass-energy formula for a black hole endowed with electromagnetic structure (EMBH) is clarified for the nonrotating case. The irreducible mass $M_{\rm irr}$ is found to be independent of the electromagnetic field and explicitly expressable as a function of the rest mass, the gravitational energy and the kinetic energy of the collapsing matter at the horizon. The electromagnetic energy is distributed throughout the entire region extending from the horizon of the EMBH to infinity. We discuss two conceptually different mechanisms of energy extraction occurring respectively in an EMBH with electromagnetic fields smaller and larger than the critical field for vacuum polarization. For a subcritical EMBH the energy extraction mechanism involves a sequence of discrete elementary processes implying the decay of a particle into two oppositely charged particles. For a supercritical EMBH an alternative mechanism is at work involving an electron-positron plasma created by vacuum polarization. The energetics of these mechanisms as well as the definition of the spatial regions in which thay can occur are given. The physical implementations of these ideas are outlined for ultrahigh energy cosmic rays (UHECR) and gamma ray bursts (GRBs).

The main objective of this article is to clarify the interpretation of the mass-energy formula [1] for a black hole endowed with electromagnetic structure (EMBH). For simplicity we study the case of a nonrotating EMBH using the results presented in a previous letter [2]. The collapse of a nonrotating charged shell can be described [2] by an exact analytic solution of the Einstein-Maxwell equations. The world surface S of the shell divides the space-time into two

Email addresses: ruffini@icra.it (Remo Ruffini), vitagliano@icra.it (Luca Vitagliano).

complementary regions: an internal one $\mathcal{M}_-$ and an external one $\mathcal{M}_+$. In spherical coordinates the line element is

$$ds^2 = \begin{cases} -f_+ dt_+^2 + f_+^{-1} dr^2 + r^2 d\Omega^2 & \text{in } \mathcal{M}_+,\ r > R \\ -dt_-^2 + dr^2 + r^2 d\Omega^2 & \text{in } \mathcal{M}_-,\ r < R \end{cases}, \tag{1}$$

where $f_+ = 1 - \frac{2M}{r} + \frac{Q^2}{r^2}$, and t_- and t_+ are the Schwarzschild-like time coordinates in $\mathcal{M}_-$ and $\mathcal{M}_+$ respectively. Here Q is the charge of the shell and M its mass-energy, measured by an observer at rest at infinity, while R is the coordinate radius separating the two regions and may be considered as a function of either t_- or t_+. $\mathcal{M}_-$ and $\mathcal{M}_+$ are static space-times; we denote their time-like Killing vectors by ξ_-^μ and ξ_+^μ respectively. $\mathcal{M}_+$ is foliated by the family $\left\{\Sigma_t^+ : t_+ = t\right\}$ of space-like hypersurfaces of constant t_+.

The splitting of the space-time into two regions $\mathcal{M}_-$ and $\mathcal{M}_+$ allows two physically equivalent descriptions of the collapse and the use of one or the other depends on the question one is studying. The use of $\mathcal{M}_-$ proves helpful for the identification of the physical constituents of the irreducible mass while $\mathcal{M}_+$ is needed to describe the energy extraction process from the electromagnetic black hole (EMBH). The equation of motion for the shell [2] is

$$\left(M_0 \tfrac{dR}{d\tau}\right)^2 = \left(M + \tfrac{M_0^2}{2R} - \tfrac{Q^2}{2R}\right)^2 - M_0^2 \tag{2}$$

in $\mathcal{M}_-$ and

$$\left(M_0 \tfrac{dR}{d\tau}\right)^2 = \left(M - \tfrac{M_0^2}{2R} - \tfrac{Q^2}{2R}\right)^2 - M_0^2 f_+ \tag{3}$$

in $\mathcal{M}_+$. M_0 is the total rest mass of the shell, R is its Schwarzschild radius and τ is the proper time along S. As remarked in [2], from the G_{tr} Einstein equation we have the constraint

$$M - \tfrac{Q^2}{2R} > 0. \tag{4}$$

Since $\mathcal{M}_-$ is a flat space-time we can interpret $-\frac{M_0^2}{2R}$ in (2) as the gravitational binding energy of the system. $\frac{Q^2}{2R}$ is its electromagnetic energy. Then equations (2), (3) differ by the gravitational and electromagnetic self-energy terms from the corresponding equations of motion of a test particle.

Introducing the total radial momentum $P \equiv M_0 u^r = M_0 \frac{dR}{d\tau}$ of the shell, we can express the kinetic energy of the shell as measured by static observers in $\mathcal{M}_-$ as $T \equiv -M_0 u_\mu \xi_-^\mu - M_0 = \sqrt{P^2 + M_0^2} - M_0$. Then from equation (2) we have

$$M = -\tfrac{M_0^2}{2R} + \tfrac{Q^2}{2R} + \sqrt{P^2 + M_0^2} = M_0 + T - \tfrac{M_0^2}{2R} + \tfrac{Q^2}{2R}. \tag{5}$$

where we choose the positive root solution due to the constraint (4). Eq. (5) is the *mass formula* of the shell, which depends on the time-dependent radial

coordinate R and kinetic energy T. If $M \geq Q$, an EMBH is formed and we have

$$M = M_0 + T_+ - \frac{M_0^2}{2r_+} + \frac{Q^2}{2r_+}\,, \tag{6}$$

where $T_+ \equiv T\left(r_+\right)$ and $r_+ = M + \sqrt{M^2 - Q^2}$ is the radius of external horizon of the EMBH. We know from the Christodoulou-Ruffini EMBH mass formula that

$$M = M_{\rm ir} + \frac{Q^2}{2r_+}, \tag{7}$$

so it follows that

$$M_{\rm ir} = M_0 - \frac{M_0^2}{2r_+} + T_+, \tag{8}$$

namely that $M_{\rm ir}$ is the sum of only three contributions: the rest mass M_0, the gravitational potential energy and the kinetic energy of the rest mass evaluated at the horizon. $M_{\rm ir}$ is independent of the electromagnetic energy, a fact noticed by Bekenstein [3]. We have taken one further step here by identifying the independent physical contributions to $M_{\rm ir}$. This will have important consequences for the energetics of black hole formation (see [5]).

Next we consider the physical interpretation of the electromagnetic term $\frac{Q^2}{2R}$, which can be obtained by evaluating the conserved Killing integral

$$\int_{\Sigma_t^+} \xi_+^\mu T_{\mu\nu}^{(\rm em)} d\Sigma^\nu = \int_R^\infty r^2 dr \int_0^1 d\cos\theta \int_0^{2\pi} d\phi\; T^{(\rm em)}{}_0{}^0 = \frac{Q^2}{2R}\,, \tag{9}$$

where Σ_t^+ is the space-like hypersurface in $\mathcal{M}_+$ described by the equation $t_+ = t = {\rm const}$, with $d\Sigma^\nu$ as its surface element vector and where $T_{\mu\nu}^{(\rm em)} = -\frac{1}{4\pi}\left(F_\mu{}^\rho F_{\rho\nu} + \frac{1}{4} g_{\mu\nu} F^{\rho\sigma} F_{\rho\sigma}\right)$ is the energy-momentum tensor of the electromagnetic field. The quantity in Eq. (9) differs from the purely electromagnetic energy

$$\int_{\Sigma_t^+} n_+^\mu T_{\mu\nu}^{(\rm em)} d\Sigma^\nu = \frac{1}{2}\int_R^\infty dr \sqrt{g_{rr}} \frac{Q^2}{r^2},$$

where $n_+^\mu = f_+^{-1/2} \xi_+^\mu$ is the unit normal to the integration hypersurface and $g_{rr} = f_+$. This is similar to the analogous situation for the total energy of a static spherical star of energy density ϵ within a radius R, $m\left(R\right) = 4\pi \int_0^R dr\, r^2 \epsilon$, which differs from the pure matter energy $m_{\rm p}\left(R\right) = 4\pi \int_0^R dr \sqrt{g_{rr}} r^2 \epsilon$ by the gravitational energy (see [4]). Therefore the term $\frac{Q^2}{2R}$ in the mass formula (5) is the *total* energy of the electromagnetic field and includes its own gravitational binding energy. This energy is stored throughout the region $\mathcal{M}_+$, extending from R to infinity.

We now turn to the problem of extracting the electromagnetic energy from an EMBH (see [1]). We can distinguish between two conceptually physically different processes, depending on whether the electric field strength $\mathcal{E} = \frac{Q}{r^2}$ is smaller or greater than the critical value $\mathcal{E}_{\rm c} = \frac{m_e^2 c^3}{e\hbar}$. Here m_e and e are the mass and the charge of the electron. We recall that an electric field $\mathcal{E} > \mathcal{E}_{\rm c}$ polarizes the vacuum creating electron-positron pairs (see [6,7,8]). The maximum value

$\mathcal{E}_+ = \frac{Q}{r_+^2}$ of the electric field around an EMBH is reached at the horizon. We then have the following:

(1) For $\mathcal{E}_+ < \mathcal{E}_{\rm c}$ the leading energy extraction mechanism consists of a sequence of descrete elementary decay processes of a particle into two oppositely charged particles. The condition $\mathcal{E}_+ < \mathcal{E}_{\rm c}$ implies

$$\xi \equiv \frac{Q}{\sqrt{G}M} \lesssim \begin{cases} \frac{GM/c^2}{\lambda_{\rm C}} \left(\frac{e}{\sqrt{G}m_e}\right)^{-1} \sim 10^{-6} \frac{M}{M_\odot} & \text{if } \frac{M}{M_\odot} \leq 10^6 \\ 1 & \text{if } \frac{M}{M_\odot} > 10^6 \end{cases}, \tag{10}$$

where $\lambda_{\rm C}$ is the Compton wavelength of the electron. Denardo and Ruffini [9] and Denardo, Hively and Ruffini [10] have defined as the *effective ergosphere* the region around an EMBH where the energy extraction processes occur. This region extends from the horizon r_+ up to a radius

$$r_{\rm Eerg} = \frac{GM}{c^2}\left[1 + \sqrt{1 - \xi^2\left(1 - \frac{e^2}{Gm_e^2}\right)}\right] \simeq \frac{e}{m_e}\frac{Q}{c^2}\,. \tag{11}$$

The energy extraction occurs in a finite number $N_{\rm PD}$ of such discrete elementary processes, each one correponding to a decrease of the EMBH charge. We have

$$N_{\rm PD} \simeq \frac{Q}{e}\,. \tag{12}$$

Since the total extracted energy is (see Eq. (7)) $E^{\rm tot} = \frac{Q^2}{2r_+}$, we obtain for the mean energy per accelerated particle $\langle E\rangle_{\rm PD} = \frac{E^{\rm tot}}{N_{\rm PD}}$

$$\langle E\rangle_{\rm PD} = \frac{Qe}{2r_+} = \frac{1}{2}\frac{\xi}{1+\sqrt{1-\xi^2}}\frac{e}{\sqrt{G}m_e}\; m_e c^2 \simeq \frac{1}{2}\xi\frac{e}{\sqrt{G}m_e}\; m_e c^2, \tag{13}$$

which gives

$$\langle E\rangle_{\rm PD} \lesssim \begin{cases} \frac{M}{M_\odot} 10^{21} eV & \text{if } \frac{M}{M_\odot} \leq 10^6 \\ 10^{27} eV & \text{if } \frac{M}{M_\odot} > 10^6 \end{cases}. \tag{14}$$

One of the crucial aspects of the energy extraction process from an EMBH is its back reaction on the irreducible mass expressed in [1]. Although the energy extraction processes can occur in the entire effective ergosphere defined by Eq. (11), only the limiting processes occurring on the horizon with zero kinetic energy can reach the maximum efficiency while approaching the condition of total reversibility (see Fig. 2 in [1] for details). The farther from the horizon that a decay occurs, the more it increases the irreducible mass and loses efficiency. Only in the complete reversibility limit [1] can the energy extraction process from an extreme EMBH reach the upper value of 50% of the total EMBH energy.

(2) For $\mathcal{E}_+ \geq \mathcal{E}_{\rm c}$ the leading extraction process is a *collective* process based on an electron-positron plasma generated by the vacuum polarization,

see Fig. 1. The condition $\mathcal{E}_+ \geq \mathcal{E}_{\rm c}$ implies

$$\frac{GM/c^2}{\lambda_{\rm C}} \left(\frac{e}{\sqrt{G}m_e}\right)^{-1} \simeq 2 \cdot 10^{-6} \frac{M}{M_\odot} \leq \xi \leq 1\,. \tag{15}$$

This vacuum polarization process can occur only for an EMBH with mass smaller than $2 \cdot 10^6 M_\odot$. The electron-positron pairs are now produced in the dyadosphere of the EMBH, a subregion of the effective ergosphere which has been defined in [12] and whose radius $r_{\rm dya}$ satisfies $\mathcal{E}_{\rm c} \equiv \frac{Q}{r_{\rm dya}^2}$. We have

$$r_{\rm dya} = \sqrt{\frac{eQ\hbar}{m_e^2 c^3}} \ll r_{\rm Eerg}. \tag{16}$$

The number of particles created [12] is then

$$N_{\rm dya} = \frac{1}{3}\left(\frac{r_{\rm dya}}{\lambda_{\rm C}}\right)\left(1 - \frac{r_+}{r_{\rm dya}}\right)\left[4 + \frac{r_+}{r_{\rm dya}} + \left(\frac{r_+}{r_{\rm dya}}\right)^2\right]\frac{Q}{e} \simeq \frac{4}{3}\left(\frac{r_{\rm dya}}{\lambda_{\rm C}}\right)\frac{Q}{e}\,. \tag{17}$$

The total energy stored in the dyadosphere is [12]

$$E_{\rm dya}^{\rm tot} = \left(1 - \frac{r_+}{r_{\rm dya}}\right)\left[1 - \left(\frac{r_+}{r_{\rm dya}}\right)^4\right]\frac{Q^2}{2r_+} \simeq \frac{Q^2}{2r_+}\,. \tag{18}$$

The mean energy per particle produced in the dyadosphere $\langle E\rangle_{\rm dya} = \frac{E_{\rm dya}^{\rm tot}}{N_{\rm dya}}$ is then

$$\langle E\rangle_{\rm dya} = \frac{3}{2}\frac{1-\left(\frac{r_+}{r_{\rm dya}}\right)^4}{4+\frac{r_+}{r_{\rm dya}}+\left(\frac{r_+}{r_{\rm dya}}\right)^2}\left(\frac{\lambda_{\rm C}}{r_{\rm dya}}\right)\frac{Qe}{r_+} \simeq \frac{3}{8}\left(\frac{\lambda_{\rm C}}{r_{\rm dya}}\right)\frac{Qe}{r_+}\,, \tag{19}$$

which can be also rewritten as

$$\langle E\rangle_{\rm dya} \simeq \frac{3}{8}\left(\frac{r_{\rm dya}}{r_+}\right)\ m_e c^2 \sim \sqrt{\frac{\xi}{M/M_\odot}} 10^5 keV\,. \tag{20}$$

Such a process of vacuum polarization around an EMBH has been observed to reach the maximum efficiency limit of 50% of the total mass-energy of an extreme EMBH (see e.g. [12]). The conceptual justification of this result needs, however, the dynamical analysis of the vacuum polarization process during the gravitational collapse and the implementation of the screening of the e^+e^- neutral plasma generated in this process. This analysis based on our present work conceptually validates the reversibility of the process and is given in [15].

Let us now compare and contrast these two processes. We have

$$r_{\rm Eerg} \simeq \left(\frac{r_{\rm dya}}{\lambda_{\rm C}}\right) r_{\rm dya}, \quad N_{\rm dya} \simeq \left(\frac{r_{\rm dya}}{\lambda_{\rm C}}\right) N_{\rm PD}, \quad \langle E\rangle_{\rm dya} \simeq \left(\frac{\lambda_{\rm C}}{r_{\rm dya}}\right)\langle E\rangle_{\rm PD}\,. \tag{21}$$

Moreover we see (Eqs. (14), (20)) that $\langle E\rangle_{\rm PD}$ is in the range of energies of UHECR (see [14] and references therein), while for $\xi \sim 0.1$ and $M \sim 10 M_\odot$,

$\langle E \rangle_{\rm dya}$ is in the gamma ray range. In other words, the discrete particle decay process involves a small number of particles with ultra high energies ($\sim 10^{21} eV$), while vacuum polarization involves a much larger number of particles with lower mean energies ($\sim 10 MeV$).

The new conceptual understanding of the mass formula presented here has important consequences for the energetics of a black hole. The expression for the irreducible mass in terms of its different physical constituents (Eq. (8)) leads to a reinterpretation of the energy extraction process during the formation of a black hole as expressed in [5]. It will certainly be interesting to reach an understanding of the new expression for the irreducible mass in terms of its thermodynamical analogues.

The energy extraction processes from an EMBH are shown here to be separated into two very different classes depending on the strength of the electromagnetic field ($\mathcal{E} \lesseqgtr \mathcal{E}_{\rm c}$). The process occurring for $\mathcal{E} < \mathcal{E}_{\rm c}$ leads to a prolonged ($\tau \sim 10^2 - 10^4 yrs$) very high energy emission $E \sim 10^{21} eV$ (see [12]). This process can be the basis for an explanation of UHECR [11]. On the other hand it is clear to us now that the process of vacuum polarization, whose key formulas are summarized in Eqs. (16), (17), (18), (19), appears more and more to be at the very heart of the solution of thirty years of problematics in modeling GRBs [13].
